Abstract. Bulk heterojunction organic thin-film solar cells utilizing soluble phthalocyanine derivatives, 1,4,8,11,15,18,22,25-octaalkylphthalocyanine (C_nPcH_2 , $n = 6, 7, 9, 10$), were investigated. Two broad peaks existing in the external quantum efficiency spectra almost correspond to the Q-band and B-band of C_nPcH_2 . The solar cell utilizing C_6PcH_2 had the best photovoltaic properties as evidenced by open-circuit voltage, short-circuit current density, fill factor, and energy conversion efficiency. Almost the same photovoltaic properties were observed in the solar cells utilizing C_9PcH_2 and $\text{C}_{10}\text{PcH}_2$. We discuss the photovoltaic properties by taking into consideration the crystal structure and electronic state of C_nPcH_2 from the results of the absorbance spectra, X-ray diffraction measurement, and polarization microscope observation. © 2012 Society of Photo-Optical Instrumentation Engineers (SPIE). 1 Introduction

Organic thin-film solar cells utilizing organic semiconductors have attracted considerable attention as next-generation solar cells¹ from the viewpoint of light weight, flexibility, and low cost. Such organic semiconductors are classified into two types: π -conjugated polymers and those having low molecular weight. Organic thin-film solar cells based on π -conjugated polymers have been investigated since the discovery of photoluminescence quenching,² photoinduced charge transfer,³ and photoconduction enhancement⁴ in π -conjugated polymer-fullerene systems. Organic thin-film solar cells with a bulk heterojunction active layer fabricated by a wet process achieved high energy conversion efficiency.^{5,6} Wet processes are also important for the large area fabrication⁷ of organic thin-film solar cells.

On the other hand, some low-molecular-weight semiconductors demonstrate high crystallinity and charge mobility by intermolecular interactions; however, they are inappropriate for wet processes because of their poor solubility in typical organic solvents. Therefore, organic thin-film solar cells with a layered¹ or p-i-n structure⁸ based on low-molecular-weight materials generally have been fabricated by thermal evaporation under vacuum. Recently, some groups have investigated solution-processable organic thin-film solar cells utilizing low-molecular-weight molecules,⁹ but device performance has still been low.

Fig. 1 Molecular structure of CnPcH₂.

The control of intermolecular interactions is one of the most important strategies for the molecular design of organic semiconductors. The introduction of appropriate substituents is effective for the realization of a large area of uniform molecular packing for organic devices. Recently, we have demonstrated high hole and electron drift mobilities of 1.4 cm²/Vs and 0.5 cm²/Vs in the crystalline phase of a mesogenic phthalocyanine derivative, 1,4,8,11,15,18,22,25-octahexylphthalocyanine (C6PcH₂, shown in Fig. 1), which was evaluated by means of time-of-flight (TOF) measurements.^{10,11} C6PcH₂ can be spread on a substrate from the solution and exhibits a mesogenic phase within a certain temperature range,¹² which indicates that it can be used as a low-molecular-weight donor material for film fabrication by a solution process and for realizing high-performance bulk heterojunction organic solar cells.

C6PcH₂ could be mixed in a conventional solvent with a typical acceptor molecule, such as 1-(3-methoxy-carbonyl)-propyl-1-1-phenyl-(6,6)C61 (PCBM), and the films fabricated by a solution process are available as a bulk heterojunction active layer in organic solar cells. Recently, we reported on a simple organic solar cell with bulk heterojunction of C6PcH₂ and PCBM fabricated by spin-coating, and demonstrated the high energy conversion efficiency of 3.1% and external quantum efficiency (EQE) higher than 70% at the Q-band region.¹³ Moreover, we reported on the active layer thickness dependence, hole transport buffer layer dependence, and tandem structure in an organic thin-film solar cell utilizing C6PcH₂.¹⁴

The properties of organic semiconductors, such as poly(3-alkylthiophene), strongly depend on the alkyl-substituent length.¹⁵ Therefore, alkyl-substituent length must be an important parameter for determining the electrical properties of CnPcH₂. Actually, C8PcH₂ exhibited different alignment and electrical properties than C6PcH₂.^{16,17} In this paper, we report on the alkyl-substituent length dependence of CnPcH₂ for simple bulk heterojunction organic solar cells.

2 Experimental Details

CnPcH₂ was synthesized according to the literature¹⁸ with slight modifications and fully purified by column chromatography (silica-gel with toluene as eluent) followed by repetitive recrystallization from toluene-methanol (1:2) solution. PCBM was purchased from Frontier Carbon Ltd.

The poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS, Baytron P VP AI 4083) was spin-coated onto an indium-tin-oxide (ITO)-coated quartz substrate at 1000 rpm for 60 s by using an aqueous solution diluted with the same volume of isopropanol and was dried at 100°C for 10 min in an oven under atmospheric conditions. The thickness of the PEDOT:PSS layer was estimated to be approximately 60 nm. The thickness was estimated by atomic force microscopy.

CnPcH₂ and PCBM were dissolved in chloroform solvent, and the composite ratio of CnPcH₂:PCBM was 2:1 by weight.¹³ The CnPcH₂:PCBM mixed solution was spin-coated onto the PEDOT:PSS layers at 500 rpm for 60 s in a glove box filled with argon gas. The thickness of the active layer was estimated to be approximately 150 nm.

An aluminum layer as a counter electrode to the ITO was deposited onto the composite layers through shadow masks by thermal evaporation under a pressure of approximately 10⁻⁴ Pa. The evaporation speed and thickness of the Al layer were approximately 5 Å/s and 80 nm, respectively. The active area of the solar cell was 2 × 2 mm².

The absorbance spectra were measured using a spectrophotometer (Shimadzu UV-3150). X-ray diffraction (XRD) patterns were measured using a Rigaku X-ray diffractometer (RINT

1100). The polarizing photomicrographs were measured by using a polarized optical microscope (Olympus BX50).

Carrier mobility was determined by the time-of-flight (TOF) technique. A N_2 -pulsed laser (337 nm, 800 ps) was used to generate the photocarrier. The dc bias was applied by batteries. Transient photocurrents were detected by a digital oscilloscope (Hewlett Packard Infinium 54820A) with the help of a wide-band preamplifier. The mobility, μ was calculated by the equation $\mu = d^2/V\tau_s$, where d , V , and τ_s are sample distance, applied bias, and the transit time, respectively.

The photocurrent spectra were measured with a programmable electrometer (Keithley 617S) by using a xenon lamp light passing through a monochromator as a light source, and EQE was estimated for each incident light wavelength using the equation $EQE(\%) = 1240 \times I(A/cm^2) \times 100/(\lambda(nm) \times P_{in}(W/cm^2))$, where I is the photocurrent density and λ is the wavelength of incident light. The current-voltage characteristics were measured with a high-voltage-source measurement unit (Keithley 237) under AM1.5G (100 mW/cm²) solar-illuminated conditions. From the current-voltage characteristics under AM1.5G, the FF and energy conversion efficiency (η_e) were estimated according to the following definitions: $FF = I_{max} V_{max}/I_{sc} V_{oc}$ and $\eta_e = I_{sc} V_{oc} FF/P_{in}$, where I_{max} and V_{max} are the current density and voltage at the maximum output power, respectively; V_{oc} is the open-circuit voltage; I_{sc} is the short-circuit current density; and P_{in} is the intensity of the incident light. The current-voltage characteristics and EQE spectra were measured in a vacuum at room temperature.

3 Results and Discussion

Organic molecules such as porphyrins, phthalocyanines, and their derivatives exhibit anomalous optical characteristics because of their molecular ring structures. It is well known that they possess two kinds of energy bands, Q-band and B-band, in the case of phthalocyanines.¹⁹

Figure 2(a) shows the absorption coefficient spectra of C_nPcH_2 molecules in a chloroform solution. The concentration of solution is 1×10^{-5} mol/L, and the optical path length is 1 cm. Figure 2(b) shows the absorbance spectra of C_nPcH_2 thin films with thickness of 150 nm. The absorption coefficient spectra were independent of substituent length in a solution condition, and the absorption peak wavelengths of the Q-band were 700 and 730 nm. It is thought that the photoabsorption originates from the electronic transition of the ring π -conjugation on phthalocyanine and that the electronic energy states are independent of the substituent length in an isolated condition in the solution.

The absorbance spectra of thin films at the Q-band region differed between C_6PcH_2 and the other C_nPcH_2 . The absorption peak wavelengths at the Q-band region of C_6PcH_2 were 670 and 740 nm, and those of the other C_nPcH_2 thin films were split around 640 and 770 nm. Moreover, the absorbance peak of C_6PcH_2 was 0.75, and that of the other C_nPcH_2 was about 0.5. It might be indicated that the different alignment of molecules in the C_6PcH_2 film and the other C_nPcH_2 films contribute to each electronic state.

Fig. 2 (a) Absorption coefficient spectra of C_nPcH_2 solution whose solvent is chloroform and (b) absorbance spectra of C_nPcH_2 thin films, the thickness of which was 150 nm on quartz substrate.

Fig. 3 (a) EQE spectra and (b) current density-voltage characteristics, with the solar cells under AM1.5G (100 nW/cm²) solar-illuminated conditions, with ITO/PEDOT:PSS/CnPcH₂:PCBM/Al structures.

Figure 3(a) shows the EQE spectra of the solar cells with a CnPcH₂:PCBM active layer. Two broad peaks that almost correspond to the absorbance spectra in Fig. 2(b) are visible in the EQE spectra. The EQEs at both the 670 and 740 nm regions of the solar cell utilizing C6PcH₂ were around 50% in spite of the different absorbance. Though the incident light of 740 nm was efficiently absorbed around the film surface, the generated charges could not reach the counter electrode.

The current-voltage characteristics of the solar cells utilizing CnPcH₂ under the AM1.5G (100 mW/cm²) solar-illuminated condition are shown in Fig. 3(b). The highest photovoltaic properties in all parameters of V_{oc} , I_{sc} , FF, and η_e were observed in the solar cell utilizing C6PcH₂. The performance parameters of the solar cells utilizing CnPcH₂ are summarized in Table 1. It is thought that the difference in V_{oc} also suggests that the electronic states between C6PcH₂ and the other CnPcH₂'s are different.

Figure 4 shows the XRD patterns of the CnPcH₂:PCBM bulk heterojunction films. In the XRD pattern of C6PcH₂, a large diffraction peak corresponding to the distance of the hexagonal column was observed at around $2\theta = 4.86$ deg, and the second to the fourth harmonic diffraction peaks were also observed. It is thought that C6PcH₂ formed hexagonal columnar structures with large domains in the bulk heterojunction film. On the other hand, in XRD patterns of the other CnPcH₂'s, the diffraction intensities were weaker than those of C6PcH₂, and two large diffraction peaks corresponding to the rectangular columnar structure appeared at around $2\theta = 4.27$ and 4.78 deg in C7PcH₂, $2\theta = 3.96$ and 4.25 deg in C9PcH₂, and $2\theta = 3.65$ and 4.49 deg in C10PcH₂. Moreover, many small diffraction peaks were observed. These observations indicate that C6PcH₂ has several domains with single hexagonal columnar alignment and that the other CnPcH₂'s have many domains with various alignments mainly including the rectangular columnar alignment. In the rectangular structure, the column distance should be longer than the hexagonal structure, and the carriers are not transported easily between columns. As a result, the differences in the crystalline structure, such as the domain size of single alignment and the column distance, must be the main reason for the superiority of the electrical properties in C6PcH₂:PCBM bulk heterojunction film.

Figure 5 shows polarizing photomicrographs of CnPcH₂ at 25°C between ITO-coated glass substrates under cross-Nicol conditions. The cell gap between ITO-coated glass substrates is about 15 μm . In C6PcH₂ many large crystal domains of more than 200 μm in length were observed. The high ambipolar carrier mobility, 1.08 cm²/Vs for hole and 0.5 cm²/Vs for

Table 1 Alkyl-substituent length dependence of performance parameters in current density-voltage characteristics of solar cells with ITO/PEDOT:PSS/CnPcH₂:PCBM/Al structures under AM1.5G (100 mW/cm²) solar-illuminated conditions.

Material of active layer	V_{oc} (V)	I_{sc} (mA/cm ²)	Fill factor	η_e (%)
C6PcH ₂	0.80	6.75	0.410	2.22
C7PcH ₂	0.66	4.82	0.290	0.92C9PcH ₂
C9PcH ₂	0.63	1.90	0.284	0.34
C10PcH ₂	0.59	1.81	0.293	0.31

Fig. 5 Polarizing photomicrographs of (a) C6PcH₂, (b) C7PcH₂, (c) C9PcH₂, and (d) C10PcH₂ at temperature of 25°C between ITO-coated glass substrates (cell gap, about 15 μm) under cross-Nicol conditions.

electron, was evaluated by the TOF technique. In the other C_nPcH₂'s, however, many small domains were observed, and carrier mobility could not be evaluated by the TOF technique, because of the dispersive decay curves of the transient. It is thought that the deep carrier trap at domain boundaries must be one reason for the dispersive decay curves of transient photocurrent observed in C7PcH₂, C9PcH₂, and C10PcH₂. It is considered that the photovoltaic properties of the solar cell utilizing C6PcH₂ are the highest because of the excellent electrical properties of large crystal domains with single hexagonal columnar structure alignment.

4 Conclusion

Bulk heterojunction organic thin-film solar cells utilizing the soluble phthalocyanine derivatives C6PcH₂, C7PcH₂, C9PcH₂, and C10PcH₂ were investigated. We found that the absorption

coefficient spectra were independent of substituent length in a solution condition and that the electronic energy states are independent of substituent length in an isolated condition in the solution. The absorbance spectra of thin films at the Q-band region differed between C6PcH₂ and the other CnPcH₂'s, however, and the different alignment of molecules in the C6PcH₂ film as compared with the other CnPcH₂ films contributes to each electronic state. Two broad peaks exist in the EQE spectra, which almost correspond to the Q-band and B-band of CnPcH₂. The solar cell utilizing C6PcH₂ has the highest photovoltaic properties in all parameters of V_{oc} , I_{sc} , FF, and η_e . Almost the same photovoltaic properties were observed in the solar cells utilizing C9PcH₂ and C10PcH₂. From the results of XRD measurement and polarization microscope observation, we found that C6PcH₂ formed a hexagonal columnar structure and had many large crystal domains of more than 200 μm in length. On the other hand, other CnPcH₂'s formed a rectangular columnar structure and had many small domains with various alignments. The crystalline structure accounts for differences in the electrical properties of all CnPcH₂'s and makes C6PcH₂:PCBM bulk heterojunction film superior; therefore, the solar cell utilizing C6PcH₂ displays the best photovoltaic properties.
